by Daniel Soler Viladrich

Transition metals are difficult to compute as their electronic rearrangements during simulations are important to obtain accurate results. Implying not only a big computational cost but a great time expenditure for all researchers around the world. This is not a problem if there is time to spare, but certainly, not the most optimum approach for a first qualitative analysis of a system, where the aim is to look for simplicity and effectiveness to get some fast insight. This is when Cationic Dummy Atom Software takes a key role, not just allowing researchers to run a transition metal system simulation within a day but to obtain some first essential information about their project, also being able to capture geometry distortion and ligand exchange in the case it occurs.

# *Acknowledgements*

I would like to use this section to thanks all people who have been involved in this project.

My warmest thanks to my project tutor and supervisor Prof. Jean-Didier Maréchal to give me the opportunity and guidance along the way.

Also, my special thanks of gratitude to Jaime Rodriguez, who gave me the golden opportunity to learn from him, coming to know about so many new things.

Nevertheless, I am also grateful to my tutor Dr. Carles Navau for their feedback, cooperation and support.

I would like to express my deepest appreciation to all Insilichem members, specially Lur, Josepe, Sergi and David Teixé whose contribution in stimulating suggestions and encouragement, helped me to finalise my project.

Last but not least, I would like to thank my girlfriend, parents and friends for accepting nothing less than excellence from me.

# Chapter 1

## Introduction

In this thesis, metallic systems are simulated over time with the innovative cationic dummy atoms software (CADAS) in the hope of improving the understanding of transition metals properties in terms of their structure and the microscopic interactions between them and their ligands. Which could finally lead to faster but still accurate predictions for the comprehension of the world.

### 1.1 Molecular Modelling

With the aim to achieve this grand goal, Molecular Modelling is needed, which acts as a bridge between microscopic world and macroscopic properties by approximating the interaction between molecules, usually derived from a potential energy, to obtain bulk properties predictions.

That is the main reason why Molecular Modelling has been considerably developed in the last centuries creating many opportunities of reaching new knowledge.

#### 1.1.1 Historical Overview

Everything started between 1858 and 1861, when the three chemists Archibald Scott Couper, Friedrich August Kekulé von Stradonitz, and Aleksandr Mikhailovich Butlerov independently introduced the general rules of valence for organic chemistry, and the first written structures involving chains of carbons with lines drawn as "bonds" to substituent atoms and groups [1]. Also in 1861, Johann Josef Loschmidt produced the first "correct" structure of benzene. And in 1874 Jacobus Henricus van't Hoff and Joseph Achille LeBel determined that carbon compounds have tetrahedral geometry [2].

In the earliest twentieth century the concept of forcefield appeared, from vibrational spectroscopy, which considered the forces acting between every pair of atoms in the molecule, or in a lattice in the case of ionic crystals. However, this concept was not embraced by the physics and chemistry community until more quantitative approaches arose.

Despite the inspired work described before this new computational concept did not yet widely influence the thinking of the chemical community. This changed abruptly in 1950 with the publication of Barton's short note on how the conformations of steroids affect their chemistry [3], which laid the foundation of conformational analysis. From then onward, an appreciation of the three-dimensional aspect became crucial to understanding structure, stability, conformation and reactivity.

In the same year, a group of scientists from Los Alamos published their studies of, "Equation of State Calculations by Fast Computing Machines [4]". This work, carried out a computed-based Monte Carlo methods, established the Metropolis algorithm (from the first-named author) for simulated annealing, and was the ancestor of molecular dynamics calculations.

Following the earlier successes of Monte Carlo simulations, in 1957, Alder and Wainwright used an IBM 704 computer to simulate perfectly elastic collisions between hard spheres. Later in 1964, Rahman published landmark simulations of liquid argon that used a Lennard-Jones potential where calculations matched well with experimental data. Since then, molecular dynamics (MD) is frequently used to refine three-dimensional structures of proteins and other macromolecules based on experimental constraints from X-ray crystallography or NMR spectroscopy.

In the last few years, molecular dynamics have been greatly improved allowing the influence of chemical effects, electronegativity, and hyperconjugation on molecular structure and properties. Thus, being able to simulate more successfully metallic systems, catalytic and surface reaction as Yang Jiang and Tianwei Tan did in 2015 with a refined dummy atom model of ion magnesium as shown in figure 1.1.

FIGURE 1.1: Refined Dummy Atom Model of  $Mg^{2+}$  by Simple Parameter Screening Strategy with Revised Experimental Solvation Free Energy

Having said that, there is still much to do in understanding transition metal's behaviour. Therefore, the purpose of this work is to present a new molecular modelling tool to give researchers a better opportunity to achieve this.

Nevertheless, before presenting the software one must have a general overview on the theory behind the steps that have built up to the development of this work.

### 1.1.2 Atomic description level

Inside molecular modelling several different methods can be found. Their applicability depends on the type and atomic description of the system we study.

For quantitative calculations and accuracy, quantum mechanics is the way to go, as model electronic rearrangements during a chemical reaction are essential for those parts of the system that are involved in the reaction. For a less accurate but faster result Molecular Mechanics is enough, the system is Newtonianly treated and no electron distribution, in other words, polarization is allowed. For something in between, one could use a hybrid method where most part of the system would be studied classically but certain atoms from the active site would be held under the quantum mechanic laws.

#### 1.1.2.1 Quantum Mechanics

Quantum Mechanics stem from the Schrodinger equation [1.1](#) first brought to light in the 1920's.

$$i\hbar \frac{\partial}{\partial t} \psi(r, t) = \left[ \frac{-\hbar^2}{2\mu} \nabla^2 + V(r, t) \right] \psi(r, t) \quad (1.1)$$

It treats the system as a collection of nuclei and electrons without any input to chemical bonds. Calculations are made by solving the system's Schrödinger equation. However, this equation cannot actually be solved for any but a one-electron system, and approximations need to be made. Depending on these approximations a wide scope of chemical models and methods can be found in terms of their capability and reliability and their "cost".

There are methods directly derived from theoretical principles, as Hartree Fock and DFT typically used to solve the time-independent Schrödinger equation for a multi-electron atom or molecule.

This method, as many others, makes four major simplifications.

The Born–Oppenheimer approximation where the motion of atomic nuclei and electrons in a molecule can be separated as a result of their big difference in mass.

The momentum operator is assumed to be non-relativistic.

The solution is a linear combination of a finite set of basis. The computational cost will be directly related with the type and number of basis chosen.

The mean field approximation is applied, instead of evaluating the electronic density of each electron over a nuclei, an average density function for all electrons is calculated.

With all the approximations above, the equation 1.2 is finally resolved obtaining the potential energy surface (from which we can get, for example, the equilibrium geometry and vibrational frequencies) and the electronic wave function  $\psi(\mathbf{r}; \mathbf{R})$ , which contains lots of useful information about molecular properties such as dipole moments and polarizability.

$$[T_e(r) + V_{eN}(r; R) + V_{NN}(R) + V_{ee}(r)]\varphi(r; R) = E_{el}\varphi(r; R) \quad (1.2)$$

### 1.1.2.2 Molecular Mechanics

Systems treated with molecular mechanics are made up of atoms and bonds (as opposed to nuclei and electrons), and atom coordinates are adjusted to the structural data to accommodate non-bonded interactions.

Potential energy is split in two, bonded and non-bonded interactions. The latter is traditionally studied through one, two even three body interaction terms. The former, is classically defined by forcefields, which describe the needed parameters to calculate the potential energy of a system.

The final aim is to calculate the molecular mechanics energy equation given below.

$$E_T = E_{stretching} + E_{bending} + E_{torsions} + E_{vanderwals} + E_{electrostatic} + E_{crossterms} \quad (1.3)$$

Where  $E_{stretching}$  is the energy involved in the deformation of a bond, either by stretching or compression and  $E_{bending}$  is the energy involved in angle bending.

To determine them, bonds are treated as spring using the equation 1.4 based on Hook's law.

$$E_{stretching} = \sum_{bonds} k_b(r - r_o)^2 + \sum_{angles} k_\theta(\theta - \theta_o)^2 \quad (1.4)$$

$E_{torsions}$  is the torsional angle energy, which represents the amount of energy that must be added or subtracted to the other terms to make the total energy agree with the experimental value. This one is described through the periodical function 1.5.

$$E_{torsions} = A[1 + \cos(n\tau - \phi)] \quad (1.5)$$

$E_{vanderWaals}$  is the energy related with the distance dependent interactions between atoms. On the one hand, van der Waals attraction occurs at close distance, and rapidly dies off as the interacting atoms separate a few Angstroms. On the other hand, repulsion occurs when the distance between interacting atoms becomes even slightly less than the sum of their contact radius. That is summed up on the equation 1.6, where the repulsive term diverges at short ranges and the A and B parameters control the depth and the position of the potential energy well. However, this is not the only equation that can describe this type of behaviour.

$$E_{vanderWaals} = -\frac{A_{ij}}{r_{ij}^6} + \frac{B_{ij}}{r_{ij}^{12}} \quad (1.6)$$

$E_{electrostatic}$  is the energy involved in interactions between atoms that are not directly bonded. This is modeled using a Coulombic potential. Where, electrostatic energy depends on the charge of the non-bonded atoms, their interatomic distance, and a molecular dielectric expression that accounts for the attenuation of electrostatic interactions by the environment.

By separating out the van der Waals and electrostatic terms, molecular mechanics attempts to make the remaining constants more transferable among molecules than they would be in a spectroscopic force field.

One application where MM is found is molecular dynamics simulations (MD) based on the ergodic hypothesis: Instead of calculating the partition function to obtain ensemble averages, such as energy, values are replaced by time averages over the simulation.

All of this is obviously much simpler than solving the Schrödinger equation for electron motions, but requires an explicit description of “chemical bonding”, as well as a large amount of information about the structures of molecules.

Pharmaceutical companies, research groups and many other members of the scientific community have been using MD to perform ligand dockings on the protein active site, for instance in drug design, the mechanism of inhibition of protein kinases[5] (targets for treatment of a number of diseases) has been illuminated by the use of several of this modelling methods.

## 1.2 Molecular Mechanics. Metal Systems Modelling

A big number of catalytic processes in biological systems rely on the powerful reactive properties of transition metal ions which are studied through computational approaches 1.2.

FIGURE 1.2: Different computational models of a chiral palladium-(II)-bis(trichlorosilyl) complex. <sup>TM</sup>Full QM: full quantum model(DFT with BP86 gradient corrections); <sup>TM</sup>Small QM: minimal quantum model; <sup>TM</sup>QM/MM-1: QM/MM model in which the effects of the phenyl groups of the phosphine ligand are treated on the molecular mechanics level; <sup>TM</sup>QM/MM-2: QM/MM model in which the effects of the phenyl groups of the phosphine ligand are described at the DFT level.

The theoretical modelling of chemically active transition metal centres is a notoriously difficult task. The metal-ligand interactions and the concoction of suitable analytic interaction potentials can be more complex than expected. The situation can get even more difficult by the fact that at finite temperature, the system might switch dynamically between different bonding situations which is characterized by different coordination numbers and geometries.

To represent all these behaviours several quantum mechanics methods shed light to this field in the late 1980s as new and better computational approaches were created.

The first of them was Hartree Fock, a variational method based on the Eckart theorem which states that any trial wave function will have an energy expectation value that is greater than or equal to the true ground state wave function energy corresponding to the given Hamiltonian. Because of this, the Hartree–Fock energy is an upper bound to the true ground state energy of a given molecule.

Consequently, the accuracy of the method will rely on which trial function is used on calculations. This process can be optimised by searching for the smallest expected energy value function, which usually includes effective nuclear charge to emulate the electrons shielding inside an atom. Another way to improve the trial function is to use a linear

combination of functions via which orbitals are described (even though orbital functions are known they are too complex to compute).

A few years later density functional theory (DFT) came up, this revolutionary method uses the Kohn–Sham equation, 1.7, defined by a fictitious external potential denoted as  $V_s(r)$  in which the non-interacting particles move.

$$\left[\frac{-\hbar^2}{2m} \nabla^2 + V_s(r)\right]\theta(r) = E_i\theta(r) \quad (1.7)$$

Here  $E_i$  is the orbital energy of the corresponding Kohn–Sham orbital  $\theta$ . Where the density for an N-particle system is describe by the equation 1.8:

$$\rho(r) = \sum_i^N |\theta(r)|^2 \quad (1.8)$$

The density function coming from the chosen functional will be the key player as it will define our initial density from which we will determine the energy of a system 1.9.

$$E_{tot(\rho)} = E_{kin(\rho)} + E_{ext(\rho)} + E_{H(\rho)} + E_{xc(\rho)} \quad (1.9)$$

Where  $E_{kin(\rho)}$  is the Kohn–Sham kinetic energy 1.10,  $E_{ext(\rho)}$  the energy due to external potential (usually ions) 1.11,  $E_{H(\rho)}$  the classic Hartree (or Coloumb) repulsion (e- - e-) 1.12 and  $E_{xc(\rho)}$  the exchange-correlation energy.

$$E_{kin} = \sum_1^N \int dr \phi(r)^* \frac{-\hbar^2}{2m} \nabla^2 \phi(r) \quad (1.10)$$

$$E_{ext} = \int dr v_{ext}(r) \rho(r) \quad (1.11)$$

$$E_H = \frac{e^2}{2} \int dr \int dr' \frac{\rho(r)\rho(r')}{|r - r'|} \quad (1.12)$$

Even though Kohn–Sham equation is exact, the exchange-correlation energy functional is not known explicitly. That is the main reason the method is not absolutely accurate and it is also the reason for the derivation of various exchange correlation functionals.

All in all, the two approaches above and some hybrids of both are currently the most used on metal binding enzymes modelling. Even though, due to their high computational

cost they are not feasible for large scale systems, and quantum mechanical/molecular mechanical (QM/MM) method needs to be used.

The hybrid QM/MM is a multiscale technique, which responds to two necessary requirements for the modeling of metal binding enzymes. The first is the complexity of the system and their computational cost and the second one is the realism of the model system to be as accurate as possible to reality.

Unfortunately, most MM force fields don't take into account the electronic degrees of freedom, experiencing large difficulties in describing the metal environment accurately. In addition, force fields do not account for bond breaking and forming events. To address these issues, is it necessary to move to the parameter-free quantum mechanical (QM) approaches on certain areas of the system and keep the rest under the MM laws.

Even though when aiming to describe systems qualitatively the process explained previously is severely time consuming and its computational cost is too high. In order to pose a solution to this problem MM could be used as a more efficient alternative.

### **1.2.1 Qualitative Thermodynamic Approaches**

Systems such as enzyme, substrates, solvent and counterions, are capable of taking all the requirements expressed before into account and are therefore to be preferred with respect to simplified models, which mimic only the reactive centers. Such systems may be managed efficiently by MM.

There are multiple ways to model metal ions, each of these have their associated pros and cons. Which is the best for our purpose will depend on how we want to define our system and the answers we are willing to extract.

#### **1.2.1.1 Covalent Bond Approach**

This method considers bonding between the metal centre and the ligands around, treating them as springs and using the harmonic oscillator potential to describe their behaviour.

However, this method suffers from the fact that they include predefined covalent bonds between the metal and ligands, not allowing for ligand and geometry exchange. Additionally, this approach includes several other drawbacks such as the large number of parameters to be defined and double counting of the electrostatic and Lennard-Jones interactions.

Ligand exchange does happen but in some cases they occur in a time scale of  $5 \cdot 10^{-4}$  microsecond, therefore having into account that MD time steps are normally at the femtosecond level, the bonded model is an effective approach to study these processes. This is because the time step is much larger than the ligand exchange mechanism.

#### 1.2.1.2 Non Bond Approach

On the other hand, we have got a non bond approach where metal–ligand interactions are described through electrostatic and van der Waals potentials. Thus, allowing ligand exchange.

On the downside, it appears to be inadequate when it comes to more complex situations such as multinuclear metal center systems, closely located metal ions and transition metals. In the latter case, the challenge is to obtain a parameter set that can simultaneously reproduce both solvation free energies and metal–water distances.

Nevertheless, they are very functional to study simple systems without need for big parametrisation.

#### 1.2.1.3 Hybrid Methods. Cationic Dummy Atom

In the end one realises that there are two sides of the coin, a good description of the electronic interaction or a strong bonded model. However these approaches clash, but one still wonders if it would be possible to have an in between both.

Currently the solution is the cationic dummy atom model. This model places charges between the metal ions and surrounding residues to mimic covalent bonds and offer a more sophisticated electrostatic model but still requires the tedious parametrisation of not just the metal centre, but also the charge and VdW on each site as well.

### 1.3 Cationic Dummy Atoms Software

CaDAS implements all advantages cited before finally creating a Molecular Dynamics input, whilst removing the time-wise handicap. All this is done through a light and simple interface adapted to users of any level, for the most frequently found metal centre geometries (tetrahedral, square planar, octahedron and square pyramid).

CaDAS consists of several dummy atoms that bind to the metal centre with the metal charge evenly transferred between them. This metal-dummy attachment is purely electrostatic even though it affixes the dummies to a static position with respect to the

metal, still emulating a covalent bond behaviour. In order not to loose the dummy geometry during simulation these are attached to one another creating a constraint that keeps all of them packed as in figure 1.3.

The spreading of the charges between the surrounding dummies tries to copy the charge distribution density inside the metal atom orbitals, making the non covalent character of the system more realistic.

The largest part of the software is smoothly ran on the background creating all mass, bond, angle, dihedral and charge parameters the model needs. Hence, it removes the most laborious part of the approach simplifying the process for users.

FIGURE 1.3: Pd(II) using cationic dummy atoms (CaDA).

To implement CADAS, Chimera UCSF and Tleap have been used and wrapped around python language. Both of them having a set of unique characteristics that make them essential to this software.

However, the launch of the MD simulation will be performed by an external high performance software called OpenMM.

### 1.3.1 UCSF Chimera

UCSF Chimera is a highly extensible program for interactive visualization and analysis of molecular structures and related data, including density maps, supra-molecular

assemblies, sequence alignments, docking results, trajectories, and conformational ensembles.

In addition, UCSF Chimera gives users the opportunity to work through a python shell. The UAB research group Insilichem seized this characteristic to create PyChimera, which provides access to Chimera's modules from any Python 2.x interpreter keeping the interface out of the equation.

This last tool will be one of the two major external softwares used in CaDAS, which will extract any necessary information of the system in order to create the search and orientation algorithms that will be seen later on in the methodology.

### 1.3.2 Tleap

Amber is the collective name for a suite of programs that allow users to carry out molecular dynamics simulations, particularly on bio molecules. The various parts work reasonably well together, and provide a powerful framework for many common calculations.

tLEaP is the primary program to create a new system in Amber, or to modify existing systems. Unlike xLEaP, tLEaP works without interface only using a simple command line.

Therefore, tLEaP will be in charge of building up the system coordinates and topology, in other words, the MD input.

### 1.3.3 OpenMM

OpenMM is a high performance toolkit for molecular simulation that can be used as a library, or as an application. Its extreme flexibility through custom forces and integrators and its extreme performance through GPU Acceleration, with optimizations for AMD, NVIDIA, and Intel Integrated GPUs makes the software one of the most powerful MD tools around the scientific community.

However, OpenMM is a complicated library to use and sometimes not user friendly for beginners. Hence, a new software called ommprotocol was created by Jaime Rodriguez and Jean Didier Marechal to make OpenMM MD launches simpler.

Consequently, this last program will be the one handling the MD launch.

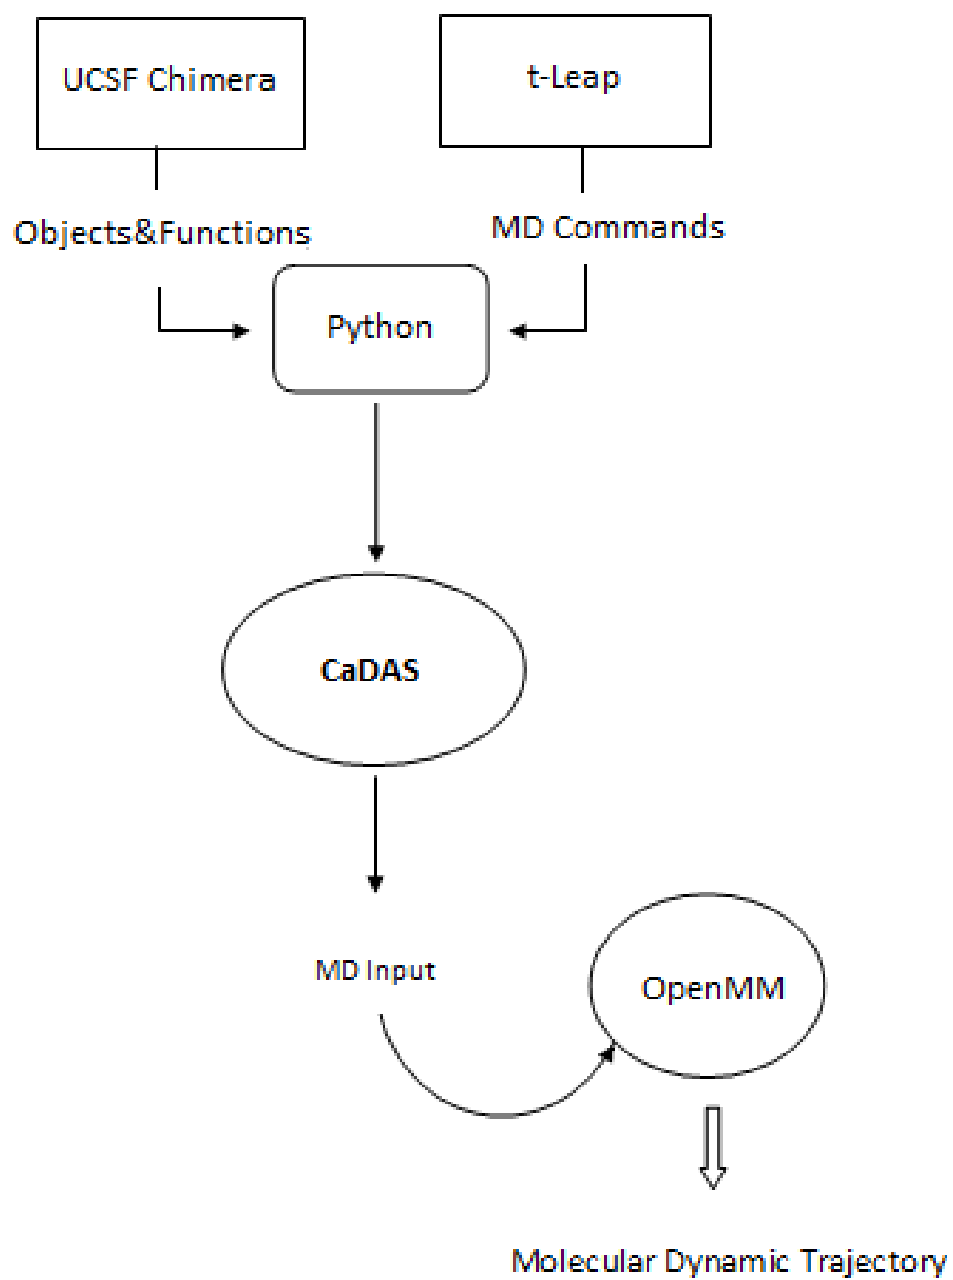

FIGURE 1.4: Software Overall Structure

## Chapter 2

# Methodology

The aim of this section is to demonstrate how this project was conducted by following the guide lines shown in the previous section.

### 2.1 CaDAS

In order to do that, the structure of the software will be broken down into three main parts. However, it would be helpful for one to understand first the general flowchart of the program.

#### 2.1.1 Flowchart

The flowchart is subdivided into three main sections as we can see in figure [2.1](#).

In the first place, the given input is a .pbd file usually obtained from the protein data bank or from another program's output, which contains the topology and coordinates of the system to be studied.

Next, two different processes are applied to the system. The aim of the first process, shown in orange in figure [2.1](#), is the addition of the dummies while conserving the chemical properties of the system. If one included the desired dummies directly, neither the mass or charges of the metal system would be the same as the original ones. This will be explained in more depth in the next section.

The second, in blue, is the acquisition of the system's physical properties such as, masses, coordinates, bond length, Van der Waals radius and number and position of its dummies.

As it was mentioned before, the anatomy of the system is fundamental in MM, to get the right description of the system which is being modelled.

Last but not least, shown in green, is the final phase of the software, where the program recollects the system anatomy and its properties from the steps before, producing the simulation input.

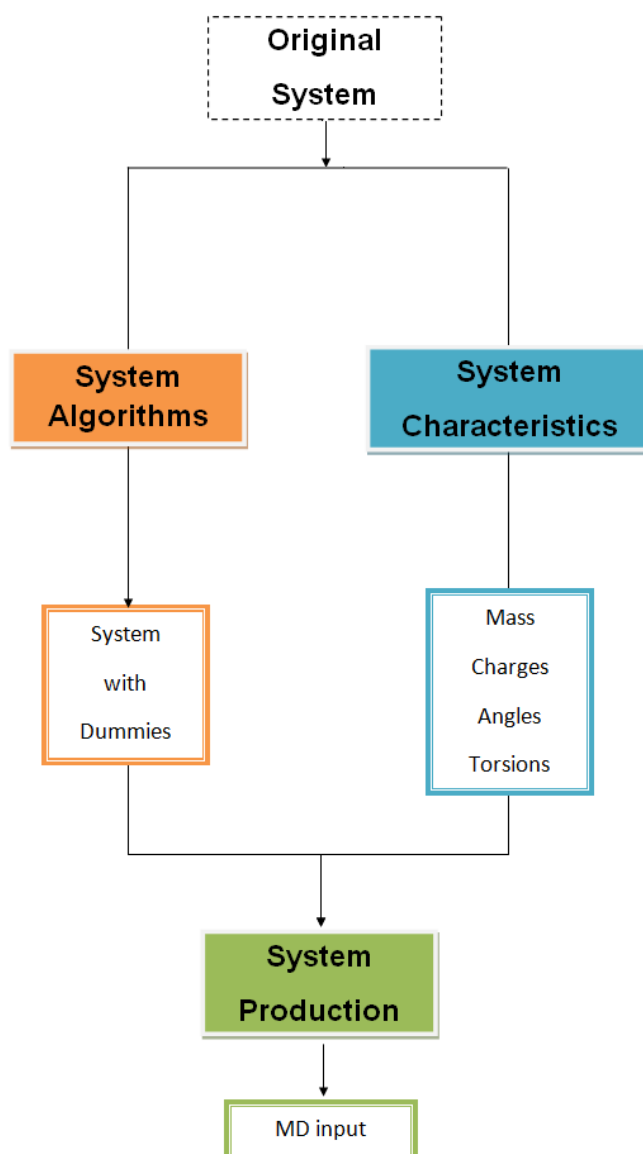

FIGURE 2.1: CaDAS Flowchart

### 2.1.2 System Algorithms

Prior to the dummies being included, their optimum position must be known to avoid problems at the very first stages of simulation. Finding out these coordinates is the main goal of this section.

On the initial step, the metal center ligands will be identified within all the other atoms in the system. Having done that, the best directions of the dummies will be determined according to the given geometry and ligand positions.

Ultimately, every dummy will be carefully placed in the system while atom types are assigned to them.

FIGURE 2.2: System Algorithms Flowchart

### 2.1.2.1 Search Algorithm

The heart of the program is a ligand-search algorithm around the metal using UCSF Chimera objects and wrapping them with python.

The algorithm starts by looking for the closest atoms around the metal. Once it is done, for this list of atoms the software does the following. First, for every atom the conditions in the list below are checked in the order which they are written. Once one of these conditions is not fulfilled the atom is discarded as a possible ligand and the function moves on to the next atom. Finally retrieving the chosen ligands.

- The atom can not be another metal. Therefore, CaDAS excludes metal-metal bridges.
- The atom valence must be greater than 5 after withdrawing the electron pair which will coordinate to the metal center. Otherwise, this pair of electrons will be placed in an inner shell being unable to participate in the formation of a chemical bond with the metal center.

---

$$\text{valence} = (\text{atomic number} - 2) \% 8 < 5$$

---

- The atom must have a lone pair or it will not be able to have any interaction with the metal center.
- The atom can not be a hydrogen since H atoms do not act as ligands.
- The coordinating distance between metal and ligand must be smaller than 4Å or the interaction between both will not be strong enough to create a chemical bond.
- The atom must still have a free coordinating place to bond with the chosen metal.
- The angle of the atom must be close to the requested geometry. Otherwise it will not be possible to create the desired model.

---

```
for neighbour in neighbours_candidates:
    if angle(neighbour, candidate_to_ligand, metal) < angle_Cutoff:
        break
```

---

### 2.1.2.2 Orientation Algorithm

The atoms that fulfil the conditions from above will be treated as ligands from the studied metal center. They will undergo an orientation process to find which is the best position to place the dummies, taking into account the desired geometry and the positions of the ligands.

This part of the code is mostly geometrical, as half of the dummies are fixed to the right position (on the line connecting the metal center and the ligand) and the others are rotated around the metal while calculating the RMSD between the ideal position and the one found for each conformation. Once all of them are explored, only the best one is reported.

Lastly, the algorithm returns the exact position of all dummies for this geometry as seen in the pseudo code below.

---

```
for direction in optimum_directions:
    direction.length = dummy_metal_bondlength #user input
    dummyposition = self.metal.labelCoord() + direction
    dummies_xyz.append(dummyposition)
return dummies_xyz
```

---

### 2.1.2.3 Geometry Algorithm

The final step is to obtain the right dummies' position with the right atom types.

An atom type is a label that defines how an atom will interact with its neighbours. In order to do that every atom type must bring angles, torsions and hybridisation associated. A mistake on these labels could lead to an undesired system topology.

To achieve the correct correlation between dummy position and type, CaDAS labels a dummy with a given type. The next step is to find the dummies that are equivalent in type, which means they are found at a specified geometry with respect to the labeled atom. The atoms that fulfilled this condition are labeled with the same type as the reference atom, as seen in figure 2.3. This is achieved by iterating through all the other dummies coordinates searching for an approximated 180 degree angle. In case there is a unique atom (only atom within its type) as in the square pyramid, a unique label is assigned to it.

This works for all the geometries of the software except the tetrahedral one, which does not need atom type assignation, due to the fact that all atoms are equivalent and consequently the same type.

FIGURE 2.3: Demonstration of the Geometry Algorithm for an octahedron

Once all dummies are set into place, the final topology of the system is extracted as a pdb file. Having done that, the system is now ready to be parameterized in the next section of the software.

### 2.1.3 System Properties

This section intends to yield the metal centre properties and not the whole system properties. To do that, two processes are applied to the original system.

First, a new virtual system including the metal center and the dummy atoms is created on the computer's RAM memory aside of the original system. Following, the virtual system is modelled at the users will by including charge on the dummies, emulating orbital density, and the metal-dummy connectivity as well as bonds between dummies, to keep them packed together. Finally, a t-leap command will record all the preceding information in a .lib file.

Second, a template file of format .frcmod, which contains all the metal system parameters such as mass, angles and torsions is filled in with the user's inputs. First, setting little portions of mass to the dummies, giving them presence (otherwise its Newtonian force would be and no movement would occur) and then, describing all the bonds, angles and torsions for each dummy type.

It is important to remember the fact that every time some portion of mass or charge is added to a dummy is at the same time deducted from the metal centre in order not to change the system's properties.

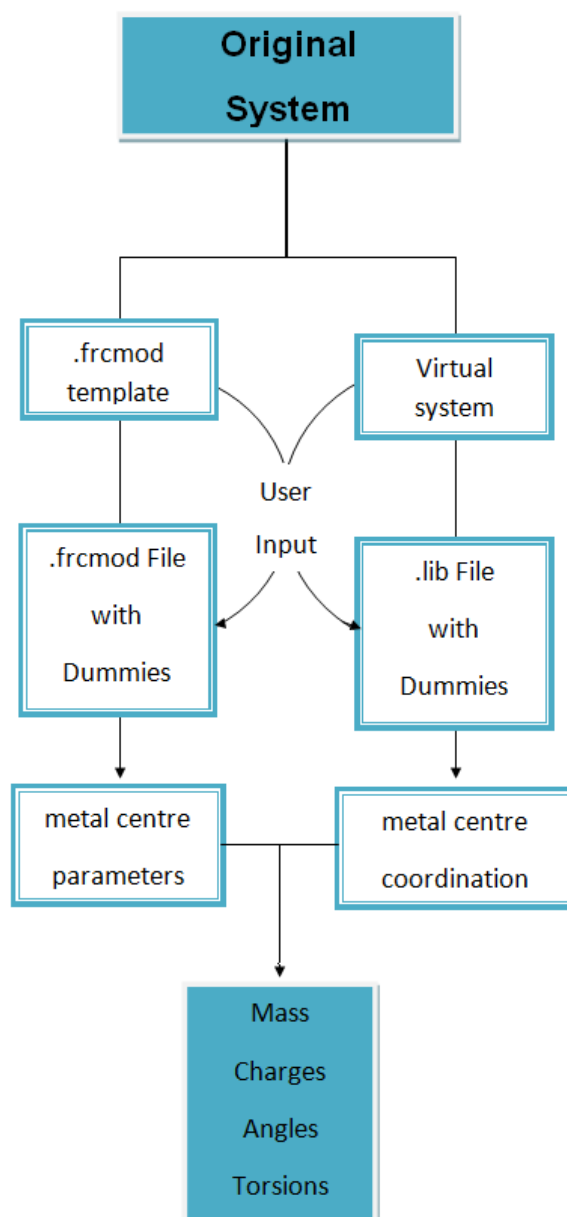

FIGURE 2.4: System Characteristics Flowchart

### 2.1.4 System Creation

The final phase of the software gathers the .lib, .frcmod and .pdb files in one single file ready to be charge by the simulation program OpenMM.

All of the above is performed with t-Leap, which combines topology, coordinates, charges and all the remaining parameters of the system to create a unique simulation input divided in two files, the final topology and system coordinates. In addition, a .log error file is outputted in case the software lacks of information of the system. All the previous is summarised in the figure 2.5.

FIGURE 2.5: System Creation Flowchart

## Chapter 3

# Results

This chapter sets out the results of the project. Initially assessing the qualitative variables to establish whether or not the software is functional. This will be followed by a quantitative analysis of all simulations. Finally ended by a critical discussion of all findings and their linkage with future for improvements.
